Abstract. This paper describes CHEM2D-H₂O, a new parameterization of H₂O photochemical production and loss based on the CHEM2D photochemical-transport model of the middle atmosphere. This parameterization accounts for the altitude, latitude, and seasonal variations in the photochemical sources and sinks of water vapor over the pressure region from 100–0.001 hPa (~16–90 km altitude). A series of free-running NOGAPS-ALPHA forecast model simulations offers a preliminary assessment of CHEM2D-H₂O performance over the June 2007 period. Results indicate that the CHEM2D-H₂O parameterization improves global 10-day forecasts of upper mesospheric water vapor compared to forecasts using an existing one-dimensional (altitude only) parameterization. Most of the improvement is seen at high winter latitudes where the one-dimensional parameterization specifies photolytic H₂O loss year round despite the lack of sunlight in winter. The new CHEM2D-H₂O parameterization should provide a better representation of the downwelling of dry mesospheric air into the stratospheric polar vortex in operational analyses that do not assimilate middle atmospheric H₂O measurements.

1 Introduction

Although the middle atmosphere (15–100 km altitude) is extremely dry when compared to the troposphere, detailed knowledge of the water vapor distribution in this region is important for a number of reasons. For example, water vapor

abundance controls the availability of odd hydrogen species for catalytic ozone loss. In addition, the emission of long-wave (terrestrial) radiation to space by water vapor is an important cooling process in the middle atmosphere. The relatively long photochemical lifetime of middle atmospheric water vapor also makes it a useful tracer for studying the dynamics of this region. Finally, the abundance of middle atmospheric water vapor is an important factor controlling the formation of both polar stratospheric clouds in winter and polar mesospheric (or noctilucent) clouds near the summer mesopause, the former being important for heterogeneous ozone loss. In more practical terms, water vapor is a fundamental prognostic variable in the dynamical cores of most numerical weather prediction (NWP) models. For these reasons, NWP and data assimilation (DA) systems whose top levels extend into the upper stratosphere and mesosphere require an accurate description of the photochemical sources and sinks of water vapor.

In general, operational requirements for timely forecasts prevent NWP systems from performing fully coupled photochemical model calculations because they are too computationally intensive. One solution to this problem is employ parameterizations based on linearization of the relevant photochemical processes (see, e.g. Cariolle and Dèqué, 1986). For a review of the development of linearized photochemistry parameterizations, see McCormack et al. (2006).

This paper describes a new linearized gas-phase water vapor photochemistry parameterization that is based on the CHEM2D zonally averaged photochemical-transport model of the middle atmosphere. CHEM2D has been successfully used to develop fast, accurate parameterizations of stratospheric ozone photochemistry (McCormack et al., 2004, 2006). MacKenzie and Harwood (2004) implemented this

type of water vapor photochemistry parameterization in a general circulation model to study trends in middle atmospheric humidity. Here we apply a similar approach to provide a suitable representation of middle atmospheric water vapor for operational NWP/DA systems.

This new water vapor photochemistry parameterization, designated CHEM2D-H₂O, has been recently implemented in the high-altitude version of the Navy Operational Global Atmospheric Prediction System (NOGAPS-ALPHA). Here we present a description of CHEM2D-H₂O as well as results from a series of NOGAPS-ALPHA forecast model simulations designed to evaluate CHEM2D-H₂O and compare its performance to a simpler one-dimensional (1-D) water vapor photochemistry scheme currently used in operational NWP/DA systems. The ultimate goal of this work is to provide global simulations of mesospheric water vapor accurate enough to identify the physical processes governing polar mesospheric cloud (PMC) formation near the summer mesopause. Section 2 gives a general overview of the CHEM2D model and middle atmospheric water vapor photochemistry. Section 3 describes the implementation of CHEM2D-H₂O in NOGAPS-ALPHA. Section 4 examines middle atmospheric water vapor fields from a series of NOGAPS-ALPHA forecast model simulations to assess the performance of CHEM2D-H₂O. Section 5 summarizes these results and outlines future research applications of CHEM2D-H₂O.

2 H₂O photochemistry in the CHEM2D model

CHEM2D is a zonally averaged (2-D) global model that features a fully self-consistent treatment of radiative, photochemical, and dynamical processes of the middle atmosphere (see, e.g., McCormack et al., 2006; McCormack et al., 2007). The model photochemistry accounts for reactions among 54 different species using reaction rates from Sander

et al. (2003). CHEM2D extends from pole to pole with grid points spaced every 4.8° in latitude; the vertical domain consists of 88 pressure levels from the surface to $p=6 \times 10^{-5}$ hPa (~ 116 km) spaced every ~ 1.3 km.

CHEM2D computes the solar UV heating above 40 km explicitly using the same spectral distribution of solar UV and absorption cross sections as in the model photolysis calculations. Details of the photolysis calculations can be found in Summers et al. (1997) and references therein. Modeled

O₂ absorption in the Schumann-Runge bands is based on the parameterization of Minschwaner et al. (1993). H₂O absorption is treated as in Siskind et al. (1994). O₂ and H₂O absorption at Lyman- α is based on the method of Lewis et al. (1983). The effects of CH₄ absorption at Lyman- α on H₂O are not considered. Solar cycle variations in irradiance are specified from 1200–8000 Å based on the measurements of Lean et al. (1997). The CHEM2D photolysis rates reported here are for solar minimum conditions. The Lyman- α irradiance at solar minimum was taken to be $3 \times 10^{11} \text{ photons cm}^{-2} \text{s}^{-1}$.

Water vapor (H₂O) in the middle atmosphere is produced directly through oxidation of stratospheric methane (CH₄) by the hydroxyl radical ($\text{OH} + \text{CH}_4 \rightarrow \text{H}_2\text{O} + \text{CH}_3$) and indirectly through a series of reactions involving the methyl radical (CH₃). The net effect is that approximately two H₂O molecules are produced for each CH₄ molecule lost in the stratosphere (e.g., LeTexier et al., 1988, and references therein). Consequently, the total number density of hydrogen throughout much of the stratosphere $Q=2[\text{CH}_4]+[\text{H}_2\text{O}]$ is a constant (neglecting the relatively small amount of molecular hydrogen, H₂). This relationship can be used to express stratospheric H₂O production in terms of H₂O abundance, which is advantageous since it eliminates the need for a prognostic CH₄ variable.

Figure 1a plots vertical profiles of individual CHEM2D CH₄ loss rates ($\text{molecules cm}^{-3} \text{s}^{-1}$) at 5° N on 15 June. Reactions (5) and (6) listed in Fig. 1a are the key reactions

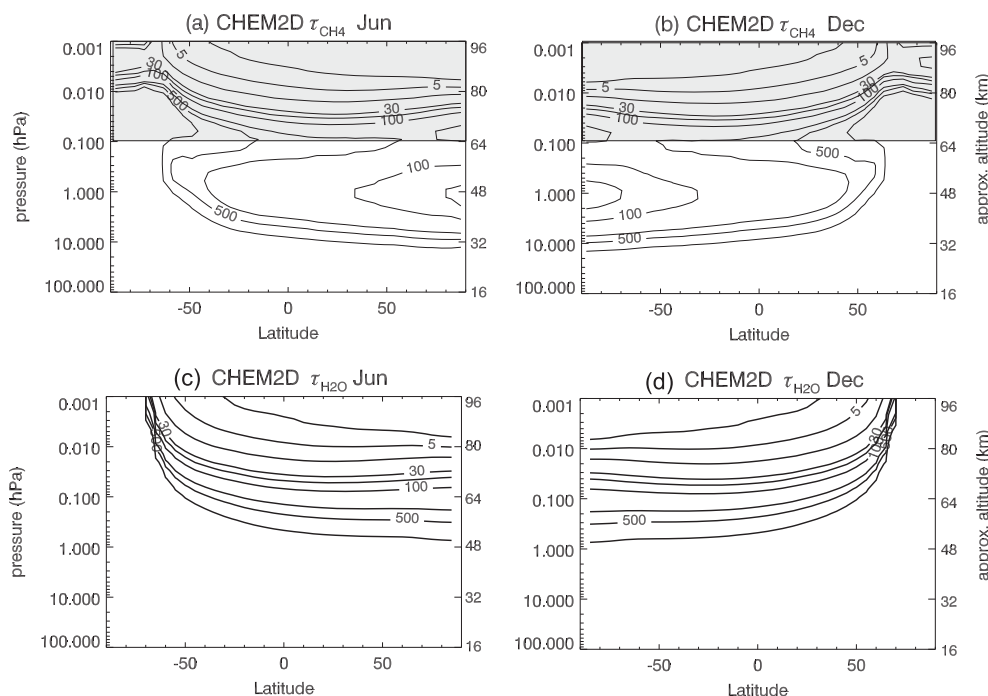

Fig. 2. Pressure-latitude plots of CHEM2D CH₄ photochemical lifetimes (in days) for (a) 15 June and (b) 15 December, and of CHEM2D H₂O lifetimes for (c) 15 June and (d) 15 December. Shading in (a) and (b) indicates region where CH₄ loss is primarily through photolysis. Contours are drawn at 3, 5, 10, 30, 50, 100, 300, 500, and 1 000 days.

responsible for stratospheric H₂O production. Above the 0.1 hPa level, CH₄ loss occurs through photolysis and does not produce H₂O directly.

As a result total hydrogen Q is not conserved in the mesosphere. Middle atmospheric H₂O is destroyed primarily through photolysis in the mesosphere by solar UV and Lyman- α radiation, yielding a number of different by-products depending on the energy of the incoming radiation (Steif et al., 1975). H₂O is lost in the stratosphere through reaction with atomic oxygen. Figure 1b plots individual CHEM2D vertical profiles of H₂O loss rates at 5° N on 15 June. The loss rates for the photolysis Reactions 1–3 in Fig. 1b are based on estimated quantum yields of 0.78, 0.10, and 0.12, respectively. These values of the quantum yields were determined from a synthesis of available laboratory measurements (Steif et al., 1975; Harich et al., 2000).

Photochemical loss rates are commonly used to infer an effective photochemical lifetime, which is a convenient way to quantify the relevant time scales for photochemistry relative to other physical processes such as advection. Figure 2 plots CHEM2D photochemical lifetimes of CH₄ and H₂O (τ_{CH_4} and $\tau_{\text{H}_2\text{O}}$ respectively) for June and December conditions throughout the middle atmosphere. The lifetimes are computed from the sum of the individual loss rates as

$$\tau_{\text{CH}_4} = \frac{[\text{CH}_4]}{\sum_{i=1}^6 L_i}, \quad \tau_{\text{H}_2\text{O}} = \frac{[\text{H}_2\text{O}]}{\sum_{i=1}^4 L_i} \quad (1)$$

where [CH₄] and [H₂O] denote CHEM2D CH₄ and H₂O abundances (molecules cm⁻³) and L_i is the loss rate (molecules cm⁻³ s⁻¹) for the individual reactions in Fig. 1.

Figures 2a and b show that the shortest CH₄ lifetimes (<2 days) are in the summer mesopause region where photolysis is the dominant loss mechanism. A secondary minimum in τ_{CH_4} is seen near the summer polar stratopause due to rapid CH₄ loss via reaction with chlorine (Reaction 4 in Fig. 1).

The shaded regions in Fig. 2 indicate where CH₄ loss is dominated by photolysis, a process that does not directly produce H₂O. The unshaded regions of Fig. 2a and b indicate where CH₄ loss produces H₂O in the stratosphere via Reactions 5 and 6 as in Fig. 1a.

Values of τ_{CH_4} for levels below 0.1 hPa exceed 50 days, indicating that stratospheric H₂O production is slow compared to typical transport timescales. As a result, including the effects of this process in typical NWP/DA systems issuing 5- to 10-day forecasts is not crucial provided that accurate stratospheric humidity data are being regularly assimilated globally. In the absence of such data, or when conducting longer free-running model simulations for seasonal prediction or climate simulations, the contribution of CH₄ oxidation to H₂O production becomes more significant.

Fig. 2c and d show that values of $\tau_{\text{H}_2\text{O}}$ in the summer hemisphere are less than 5 days above the 0.01 hPa level, indicating that H₂O photolysis is an important effect for

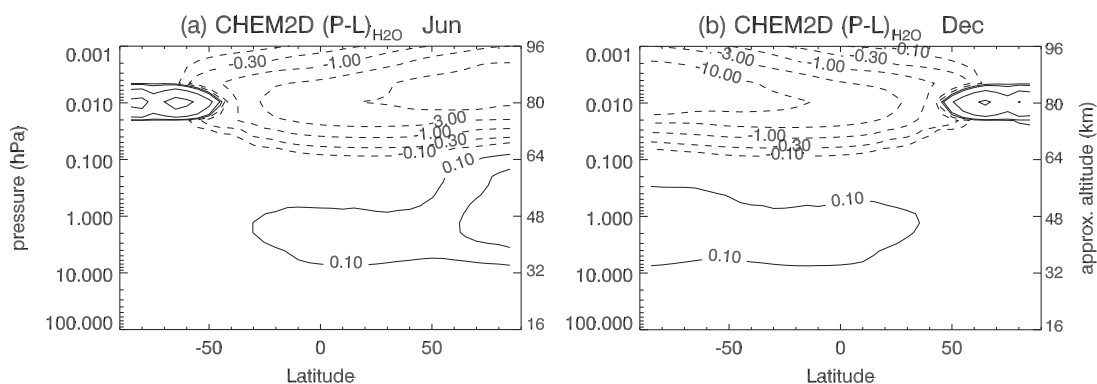

Fig. 3. Pressure-latitude plots of net CHEM2D middle atmosphere water vapor photochemical tendency $(P-L)_{\text{H}_2\text{O}}$ for (a) 15 June and (b) 15 December in parts per million (volume) per month. Contours are drawn at ± 0.1 , ± 0.3 , ± 1 , ± 3 , and ± 10 ppmv per month. Dashed contours denote negative values.

accurate medium-range forecasts in this region. Values of $\tau_{\text{H}_2\text{O}}$ near the mesopause increase rapidly poleward of 50° latitude in winter as the amount of sunlight diminishes.

To highlight the latitude, altitude, and seasonal dependences of H₂O photochemistry in the middle atmosphere, Fig. 3 plots the net CHEM2D photochemical tendency for water vapor, $(P-L)_{\text{H}_2\text{O}}$, in parts per million by volume (ppmv) per month as a function of latitude and pressure for 15 June and 15 December, where P is the net production rate and L is the net loss rate. In the stratosphere, $(P-L)_{\text{H}_2\text{O}}$ is weakly positive as a result of relatively slow H₂O production through CH₄ oxidation in the absence of water vapor photolysis at these altitudes (see Figs. 1 and 2). In the mesosphere, $(P-L)_{\text{H}_2\text{O}}$ is mostly negative due to photolytic loss, with the largest loss rates occurring near the summer mesopause region. The positive values of $(P-L)_{\text{H}_2\text{O}}$ in the winter hemisphere near 80 km poleward of 50° latitude are the result of enhanced H₂O production via the reaction $\text{OH} + \text{HO}_2 \rightarrow \text{H}_2\text{O} + \text{O}_2$. This enhancement is due to poleward transport of odd hydrogen from sunlit latitudes into polar night, where it becomes long-lived in the upper mesosphere (Brasseur and Solomon, 1986).

The values of τ_{CH_4} , $\tau_{\text{H}_2\text{O}}$, and $(P-L)_{\text{H}_2\text{O}}$ presented in this section, which vary with latitude, altitude, and month, serve as the basis for the new CHEM2D-H₂O parameterization. CHEM2D-H₂O differs from the water vapor photochemistry parameterization currently used in the European Centre for Medium Range Weather Forecasts (ECMWF) Integrated Forecast system (IFS) (Untch and Simmons, 1999; ECMWF, 2006; Feist et al., 2007), which parameterizes production via stratospheric CH₄ oxidation and loss via mesospheric photolysis as a function of altitude only, neglecting possible latitude and seasonal dependences. This method expresses the water vapor photochemical tendency as

$$\frac{\partial r}{\partial t} = k_1(r_Q - r) - k_2 r \quad (2)$$

where r is the local water vapor mixing ratio and r_Q is the equivalent total hydrogen mixing ratio.

The coefficients k_1 and k_2 are determined from analytical fits to quoted values of τ_{CH_4} in the stratosphere and $\tau_{\text{H}_2\text{O}}$ in the mesosphere, respectively, at various altitudes from Brasseur and Solomon (1986).

The coefficients k_1 and k_2 vary with altitude and are constant with latitude and season. It is assumed that r_Q has a constant value of 6.8 ppmv based on the results of Randel et al. (1998). Figure 4 plots CHEM2D values of r_Q showing this assumption holds for most of the stratosphere except winter polar regions where downward transport of dry mesospheric air occurs (LeTexier et al., 1988; Randel et al., 1998). Thus the ECMWF scheme provides a reasonable 1-D photochemical constraint on global stratospheric H₂O, but may overestimate stratospheric H₂O production in regions where conservation of r_Q breaks down.

To compare this 1D approach to the CHEM2D-H₂O parameterization, Fig. 5 plots the vertical profile of the combined photochemical lifetime, $(k_1 + k_2)^{-1}$ from the ECMWF scheme (ECMWF, 2006) along with CHEM2D values of τ_{CH_4} and $\tau_{\text{H}_2\text{O}}$ over the equator for each month of the year. Only CHEM2D values of τ_{CH_4} below the 0.1 hPa level are plotted in Fig. 5, since it is in this region where CH₄ loss leads to H₂O production. Also plotted in Fig. 5 are values of the combined CHEM2D lifetime

$$\tau^* = \frac{1}{\tau_{\text{CH}_4}^{-1} + \tau_{\text{H}_2\text{O}}^{-1}} \quad (3)$$

for each month, which are determined from the plotted values of τ_{CH_4} and $\tau_{\text{H}_2\text{O}}$ in Fig. 5.

The quantity τ^* provides a single, concise description of the time scale for H₂O photochemistry throughout the middle atmosphere that varies with latitude and season analogous to

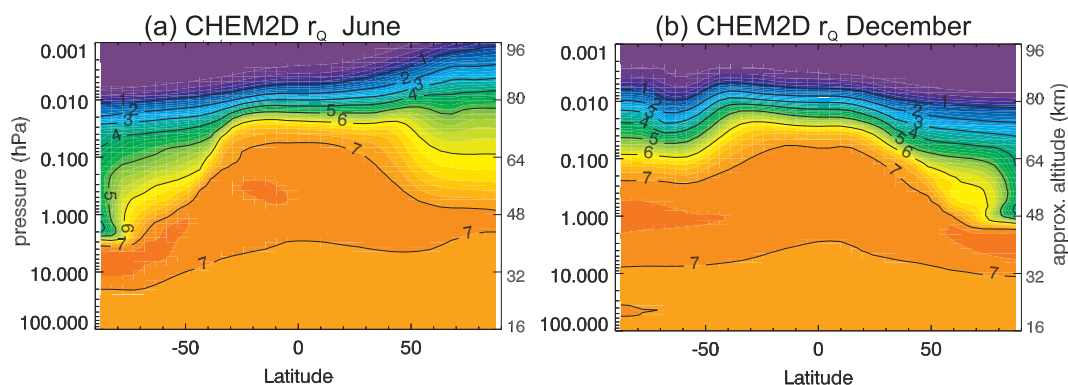

Fig. 4. Pressure-latitude plots of total hydrogen r_O (in ppmv) from the CHEM2D model for (a) 15 June and (b) 15 December. Contours are drawn every 1 ppmv.

Fig. 5. Comparison of combined photochemical lifetime (days) in the ECMWF water vapor photochemistry parameterization (black curve) with CHEM2D lifetimes τ_{H_2O} (purple curves), τ_{CH_4} (gold curves), τ^* (red curves) for all 12 months over the equator. The CHEM2D τ_{CH_4} profile is only plotted at levels where CH_4 oxidation is the dominant loss process (c.f., Fig. 1 and unshaded region in Fig. 2).

the 1-D profile of $(k_1+k_2)^{-1}$ in the ECMWF scheme. The overlapping curves in Fig. 5 indicate that there is virtually no seasonal dependence in the H_2O production and loss terms at low latitudes, in agreement with Figs. 2 and 3. As a result, CHEM2D values of τ^* for all 12 months closely match the 1D scheme's k_1^{-1} and k_2^{-1} profile.

At higher latitudes, however, seasonal variations in τ_{H_2O} and τ_{CH_4} are both quite large. As a result, τ^* also exhibits large seasonal variations at higher latitudes. To illustrate this point, Figure 6 compares values of $(k_1+k_2)^{-1}$ from the ECMWF scheme with values of τ^* at 70° N for March, June, September, and December.

Fig. 6. Comparison of combined photochemical lifetime (days) in the ECMWF water vapor photochemistry parameterization (black curve) with values of the CHEM2D effective lifetime τ^* (red curves) at 70° N on the 15th day of March, June, September, and December.

The CHEM2D model results presented in this section demonstrate that the net middle atmospheric H_2O photochemical tendency exhibits pronounced latitude and seasonal variations that should be accounted for in NWP/DA systems extending into the mesosphere. The CHEM2D- H_2O parameterization described in the following section accounts for these variations.

3 CHEM2D- H_2O in NOGAPS-ALPHA

This section describes the CHEM2D- H_2O parameterization and its implementation in NOGAPS-ALPHA. First, we briefly describe the NOGAPS-ALPHA forecast model and data assimilation components. We then provide a detailed description of the CHEM2D- H_2O scheme as it is currently used in NOGAPS-ALPHA.

3.1 NOGAPS-ALPHA description

The high-altitude NOGAPS-ALPHA NWP/DA system (Hoppel et al., 2008) is capable of assimilating middle atmosphere constituent measurements such as H₂O profiles obtained from the NASA EOS Aura Microwave Limb Sounder (MLS) (Eckermann et al., 2008, referred to hereafter as E2008). The 68-level (L68) NOGAPS-ALPHA global spectral forecast model (GSFM) initializes and advects specific humidity q at all levels from the surface to its top at 5×10^{-4} hPa. The q fields are initialized using traditional meteorological analyses from the surface up to the 200 hPa level. Above this level, the humidity fields can be initialized using either assimilated water vapor measurements for a specific date or a zonal monthly mean climatology based on measurements from the Upper Atmospheric Research Satellite (UARS) Halogen Occultation (HALOE) and MLS instruments (Randel et al., 1998; Grooß and Russell, 2005), depending on the application.

Parameterizations for moist physics in NOGAPS-ALPHA are identical to those used in the operational version of NOGAPS (Hogan and Rosmond, 1991). These include shallow cumulus mixing (Tiedtke, 1984), deep cumulus convection (Peng et al., 2004), and convective, stratiform, and boundary layer cloud formation and precipitation (Slingo, 1987; Teixeira and Hogan, 2002). For a more complete description of NOGAPS-ALPHA model physics, see McCormack et al. (2006) and E2008. Since they are designed primarily for tropospheric applications, the model's moist physics routines are only employed from the surface up to the 50 hPa level (~ 20 km). In the stratosphere and mesosphere, parameterized water vapor photochemical production and loss constrain the NOGAPS-ALPHA q fields. Without this photochemical constraint, upwelling of stratospheric air into the mesosphere would produce unrealistically high values of mesospheric humidity over forecast periods of 2–3 days. This would pose a problem for accurate forecasts of mesospheric humidity, especially in regions where humidity measurements are not assimilated.

All forecast model results in this study employ triangular truncation of the first 79 wavenumbers (T79), with a horizontal grid spacing of 1.5° in longitude and latitude on the quadratric Gaussian grid. The model uses the non-orographic gravity wave drag parameterization of Garcia et al. (2007) with the same settings as in E2008. The T79L68 model is initialized with analyzed winds, temperature, and constituents (e.g., O₃ and H₂O) produced by the NOGAPS-ALPHA DA component, which is described in detail by Hoppel et al. (2008) and E2008. From the surface to the mid-stratosphere, these NOGAPS-ALPHA analyses are based on assimilation of conventional meteorological data sets used by the operational T239L30 system.

For the June 2007 period studied here, NOGAPS-ALPHA assimilates Aura MLS temperature, O₃, and H₂O profiles (Froidevaux et al., 2006), as well as temperatures from the

Sounding of the Atmosphere Using Broadband Radiometry (SABER) instrument on the Thermosphere Ionosphere Mesosphere Energetics and Dynamics (TIMED) satellite (Kutepov et al., 2006), up to the 0.002 hPa level, (E2008). Above this level, model fields are initialized with climatology as in McCormack et al. (2006). The altitude resolution of the MLS water vapor retrievals decreases significantly with increasing altitude (Lambert et al., 2007). A Gaussian averaging kernel in the vertical direction with a full-width at half maximum value of 2 km is applied to the assimilated MLS water vapor profiles. This was done to constrain the analysis to the low resolution MLS profiles rather than risk introducing any spurious vertical structure in the H₂O fields that may arise in data-poor regions. The background error variance for water vapor in the upper atmosphere was set large enough to ensure that the analysis was highly constrained to the observations, producing a zonal mean distribution that is nearly identical to the MLS data. For further details of the assimilation system, see Hoppel et al. (2008).

A comprehensive evaluation of the NOGAPS middle atmospheric data assimilation system, including comparisons with independent observations, is currently underway. The purpose of this paper is to introduce the CHEM2D-H₂O photochemistry parameterization and evaluate its performance based on NOGAPS-ALPHA forecast model simulations of middle atmospheric water vapor. The following section describes the implementation of CHEM2D-H₂O in NOGAPS-ALPHA.

3.2 The CHEM2D-H₂O parameterization

The CHEM2D-H₂O parameterization in NOGAPS-ALPHA expresses the local time rate of change of the H₂O mixing ratio r as the difference between the zonally averaged production and loss rates computed with the CHEM2D model (see Fig. 3):

$$\frac{\partial r}{\partial t} = (P - L)_{\text{H}_2\text{O}}. \quad (4)$$

Although specific humidity q is the NOGAPS-ALPHA model's prognostic variable, for the sake of consistency with the photochemical parameterization in Eq. (2) we will use volume mixing ratio r as the moisture variable in the following discussion. Model mixing ratio r is related to q through the relation

$$r = \frac{M_d}{M_w} \frac{q}{1 - q} \quad (5)$$

where M_d and M_w are the molecular weights of dry air and H₂O, respectively.

We assume that $(P - L)_{\text{H}_2\text{O}}$ is primarily a function of r . In the mesosphere, this assumption is justified because the loss rate due to photolysis is directly proportional to the local H₂O mixing ratio. In the stratosphere, where the production rates via methane oxidation depend on the local CH₄ mixing

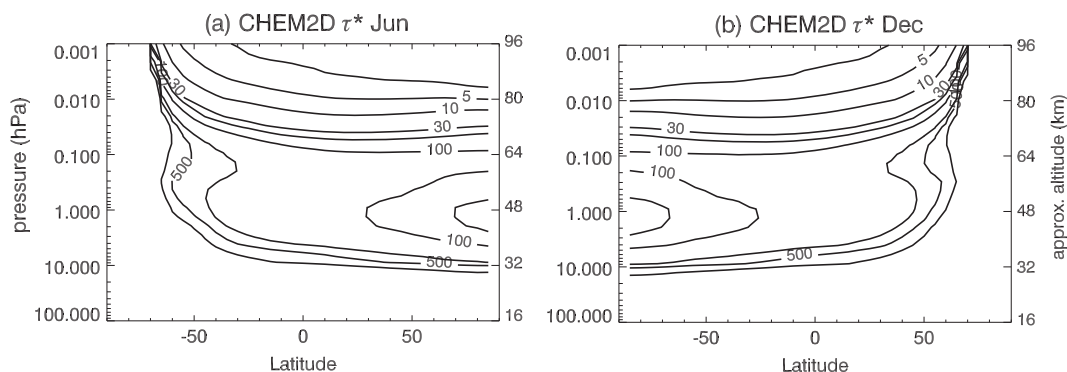

Fig. 7. Pressure-latitude plots of the effective photochemical lifetime τ^* (days) used in the CHEM2D-H₂O parameterization for (a) 15 June and (b) 15 December.

ratio, this assumption holds where the local H₂O mixing ratio can be expressed in terms of the CH₄ mixing ratio through the approximate conservation of r_Q (see Fig. 4). Where the assumption of r_Q conservation breaks down, i.e., in the winter polar stratosphere, CHEM2D values of τ_{CH_4} exceed 100 days. As shown below, accounting for these latitude and seasonal variations in H₂O production and loss ensures that the CHEM2D-H₂O parameterization only introduces photochemical tendencies in regions where its underlying assumptions are valid.

The function $(P-L)_{\text{H}_2\text{O}}[r]$ can be approximated using a first-order Taylor series expansion about a reference state such that

$$\frac{\partial r(\lambda, \phi, p, t)}{\partial t} = (P-L)_{\text{H}_2\text{O}}^o + \left. \frac{\partial (P-L)_{\text{H}_2\text{O}}}{\partial r} \right|_o (r - r^o) \quad (6)$$

where λ is longitude, ϕ is latitude, p is pressure, and “ o ” denotes the reference state.

We proceed by assuming that Eq. (6) yields an equilibrium (reference) state r^o that is the net balance between photochemical production and loss, such that any deviations from this state can be treated as small perturbations about that reference state. This follows the method used in linearized ozone photochemistry schemes, as reviewed by McCormack et al. (2006) and Lahoz et al. (2007).

Applying the expansion Eq. (6) to the ECMWF relation Eq. (2), it is straightforward to show that

$$(P-L)_{\text{H}_2\text{O}}^o = k_1 (r_Q - r^o) - k_2 r^o, \quad (7)$$

$$\left. \frac{\partial (P-L)_{\text{H}_2\text{O}}}{\partial r} \right|_o = -(k_1 + k_2) \quad (8)$$

illustrating that this approach is mathematically consistent with the 1-D parameterization in Eq. (2).

As discussed in Sect. 2 and illustrated in Figs. 5 and 6, the CHEM2D-H₂O analog of Eq. (8) is

$$\left. \frac{\partial (P-L)_{\text{H}_2\text{O}}}{\partial r} \right|_o = -(\tau^*)^{-1} \quad (9)$$

where τ^* represents the combined time scales for H₂O production via CH₄ oxidation in the stratosphere and H₂O photolysis in the mesosphere. CHEM2D model values of τ^* are tabulated as a function of latitude, pressure and season and then interpolated in space and time to the NOGAPS-ALPHA forecast model grid. Figure 7 plots the latitude and altitude dependence of τ^* for June and December conditions.

The analytical ECMWF expression Eq. (7) assumes constant total hydrogen $r_Q = 6.8$ ppmv at all altitudes. As illustrated in Fig. 4, this assumption breaks down in the upper stratosphere and mesosphere. In addition, CH₄ oxidation becomes a negligible source of H₂O in the mesosphere. Thus, for CHEM2D-H₂O we instead derive $(P-L)_{\text{H}_2\text{O}}^o$ values as a function of latitude, pressure and season directly from the CHEM2D model, examples of which were shown previously in Fig. 3. This approach enables us to compute equilibrium rates without any explicit reference to total hydrogen, and thus to extend these rates into the mesosphere where total hydrogen conservation breaks down and is dominated by photolytic loss.

Adopting an approach similar to that for the CHEM2D ozone photochemistry parameterization, or CHEM2D-OPP (McCormack et al., 2006), the specific humidity photochemical tendency in NOGAPS-ALPHA is applied by first defining a photochemical steady state value for the water vapor mixing ratio

$$r^{ss} = r^o + (P-L)^o \tau^* \quad (10)$$

so that the H₂O mixing ratio tendency can be expressed as

$$\frac{\partial r}{\partial t} = \frac{-(r - r^{ss})}{\tau^*}. \quad (11)$$

The updated mixing ratio value is computed using a standard backward-Euler solution of the form

$$r(t + \Delta t) = r(t) + [r^{ss} - r(t)] \left[\frac{\frac{\Delta t}{\tau^*}}{1 + \frac{\Delta t}{\tau^*}} \right] \quad (12)$$

and then converted to specific humidity using Eq. (5).

Table 1. H₂O photochemistry parameterizations used in the NOGAPS-ALPHA forecast model simulations.

Experiment Name	Description
EXP1	CHEM2D-H ₂ O with r^o based on UARS HALOE/MLS
EXP2	CHEM2D-H ₂ O with r^o based on Aura MLS
EXP3	ECMWF

In theory, the reference state mixing ratio r^o should correspond to the CHEM2D model mixing ratio at photochemical equilibrium. In practice, values of $r^o(\phi, p, t)$ are often specified using an observation-based climatology of middle atmospheric water vapor. Based on earlier experience with linearized ozone photochemistry parameterizations (McCormack et al., 2006; Geer et al., 2007; Coy et al., 2007), use of an observation-based reference state ensures that the linearized photochemical tendency terms will not produce large biases between the modeled and assimilated constituent values, which can negatively impact forecast skill. In this study, we perform a similar evaluation of the CHEM2D-H₂O parameterization's sensitivity to the assumed background state using two different r^o distributions. The first is based on monthly zonal mean MLS/HALOE climatology (Randel et al., 1998; Groöß and Russell, 2005) between 100–0.01 hPa combined with CHEM2D model values above the 0.01 hPa level. The second combines June zonal mean Aura MLS H₂O mixing ratios averaged over the years 2005–2008 up to the 0.002 hPa level with CHEM2D model values above this level. Solar UV fluxes in the CHEM2D model were set to solar minimum levels following Lean et al. (1997) to match June 2007 conditions.

Figure 8 compares these two r^o distributions. The Aura MLS H₂O mixing ratios in Fig. 8b are generally higher than the UARS-based values in Fig. 8a throughout the Northern Hemisphere extratropical upper mesosphere. The results presented in the following section demonstrate how these differences can affect 10-day forecasts of middle atmospheric H₂O.

4 Results

Table 1 lists three sets of NOGAPS-ALPHA forecast model simulations, designated EXP1, EXP2, and EXP3, used to evaluate the new CHEM2D-H₂O parameterization. EXP1 employs CHEM2D-H₂O with the UARS-based r^o for the month of June (see Fig. 8a). EXP2 employs CHEM2D-H₂O with the Aura MLS-based r^o for June (Fig. 8b). EXP3 uses the 1D water vapor photochemistry parameterization (2) currently used in the operational ECMWF IFS. These three sets of simulations each consist of five 10-day forecasts initialized on 5, 10, 15, 20, and 25 June 2007, encompassing the period when PMC's were observed in the Arctic region (E2008). The EXP1, EXP2, and EXP3 simulations all use the same sets of initial conditions.

We first examine the performance of CHEM2D-H₂O using the UARS-based reference state (EXP1). Figure 9a plots the water vapor mixing ratio initial conditions for 00:00 UTC on 5 June 2007, which are based on the assimilation of Aura MLS Version 2.2 (V2.2) H₂O profiles between 100–0.002 hPa (~16–90 km) combined with CHEM2D model values of the H₂O above the 0.002 hPa level (see E2008 for details). Note that EXP1, EXP2, and EXP3 simulations all use the same sets of initial conditions.

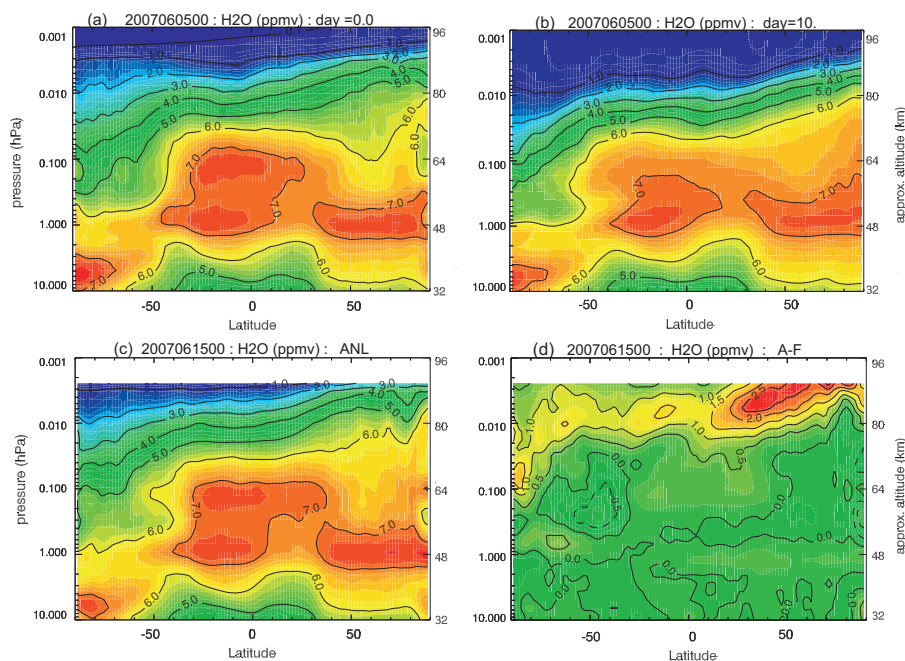

Fig. 9. Pressure-latitude plots of (a) NOGAPS-ALPHA analyzed zonal mean H₂O mixing ratios for 00:00 UTC 5 June 2007; (b) zonal mean forecast model H₂O mixing ratios at day 10 of the EXP1 model simulation initialized 00:00 UTC 5 June and valid 00:00 UTC 15 June 2007 (c) zonal mean NOGAPS-ALPHA analyzed H₂O at 00:00 UTC on 15 June 2007; (d) differences in H₂O mixing ratios between the 10-day forecast (F) in (b) and the analyzed (A) values in (c). Solid and dashed contours denote positive and negative differences, respectively.

Figure 9b plots the model H₂O mixing ratios on day 10 of the EXP1 simulation valid 15 June at 00:00 UTC. A comparison of Fig. 9b with Fig. 9a shows that the major differences in NOGAPS-ALPHA zonal mean H₂O after 10 days are: (1) a decrease at all latitudes above the 0.01 hPa level (~82 km); (2) an increase near 0.1 hPa (~65 km) poleward of 50° N; (3) a decrease over high southern latitudes between 1.0–0.1 hPa. The high latitude changes are consistent with upwelling (downwelling) of moist (dry) air in the summer (winter) polar mesosphere. The broad decrease above the 0.01 hPa level is the result of the parameterized photolysis of H₂O.

Figure 9c plots the zonal mean NOGAPS-ALPHA analyzed H₂O mixing ratios valid on 00:00 UTC 15 June 2007. This and all following plots of analyzed H₂O extend to 0.0025 hPa, which is the closest vertical level to the 0.002 hPa upper limit for scientifically useful MLS H₂O measurements (Froidevaux et al., 2006). Since NOGAPS-ALPHA analyzed H₂O is completely constrained by the MLS measurements, the analyzed zonal mean values are essentially the same as a zonal mean estimated directly from the daily MLS data. Comparison of the analyzed H₂O with the 10-day fields from EXP1 (Fig. 9b) shows large differences poleward of 30° N above the 0.01 hPa level, where the analyzed values are much higher than the modeled values. Figure 9d plots the differences between the zonal mean ana-

lyzed H₂O and 10-day forecast H₂O. After 10 days the EXP1 model simulation underestimates the zonal mean H₂O mixing ratio throughout the northern extratropical upper mesosphere by more than 2 ppmv. This is the same region where the UARS-based and Aura MLS-based r^o distributions differ substantially (Fig. 8), and where photolytic loss dominates (Fig. 3).

As mentioned in the previous section, the performance of the CHEM2D-H₂O parameterization can be affected by the choice of the background reference state r^o because it relaxes the forecast model H₂O mixing ratios in the upper levels toward the reference state value r^o . In practice, the water vapor distribution used to represent r^o should be chosen so as to avoid any systematic bias between the prognostic humidity variable and the assimilated humidity fields used to initialize and update the forecast system (see, e.g. Coy et al., 2007). Systematically low values of r^o , such as those seen in Fig. 8a, can lead to an overestimate of the H₂O loss in the northern summer upper mesosphere. This may help explain why the 10-day EXP1 forecast underestimates the H₂O mixing ratio compared to the analyses (Fig. 9d) in the northern extratropical upper mesosphere.

To investigate this possibility, we isolate the effect of parameterized water vapor photochemistry by taking the difference between the model mixing ratio r and a passive humidity tracer r_{pass} , which uses the same initial conditions as r

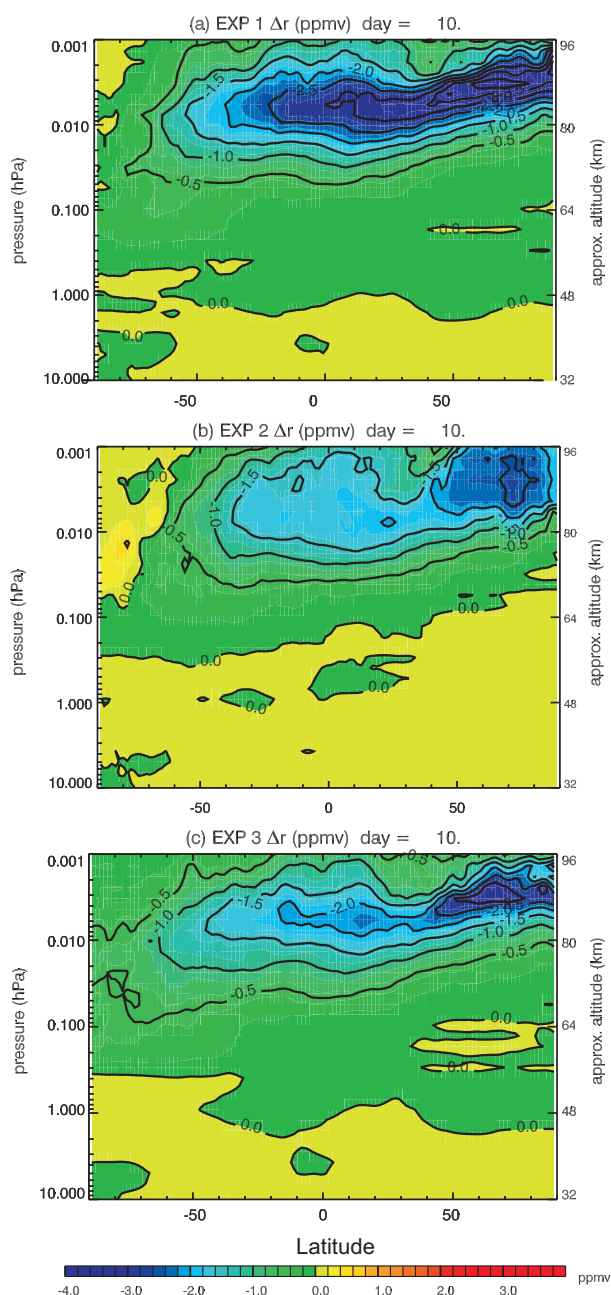

Fig. 10. Zonal mean values of Δr , the difference between NOGAPS-ALPHA model prognostic H₂O and passive (i.e., no photochemistry) H₂O on day 10 of the (a) EXP1, (b) EXP2, and (c) EXP3 simulations initialized 00:00 UTC 5 June 2007.

but is not subject to parameterized photochemistry and moist physics. In the troposphere and lowermost stratosphere, the lack of moist physics in the passive humidity field produces huge differences between r and r_{pass} (not shown). In the upper stratosphere and mesosphere, differences between r and r_{pass} are due primarily to the effect of the CHEM2D-H2O parameterized photochemistry acting on r .

Figure 10 plots zonal mean values of the difference $\Delta r = r - r_{\text{pass}}$ throughout the middle atmosphere on day 10 of EXP1, EXP2, and EXP3 simulations initialized 00:00 UTC 5 June 2007. In all three simulations, the effects of the parameterized photochemistry on the model H₂O after 10 days are relegated to the upper mesosphere. Specifically, values of Δr are negative throughout the Northern Hemisphere between 0.03–0.001 hPa, consistent with H₂O loss via photolysis (e.g., Fig. 5) that peaks at high summer latitudes. The extension of negative values of Δr across the equator and into the winter hemisphere is a consequence of photochemically-processed air with lower mixing ratio r being transported from the northern summer mesosphere to the southern winter hemisphere by the mean meridional circulation. Since the timescale for H₂O production via CH₄ oxidation is >50 days in most of the stratosphere (see Fig. 5), values of Δr after 10 days in Fig. 10 are quite small in magnitude throughout the stratosphere.

Comparing the amount of photochemical loss among the three different simulations in Fig. 10, we find that the greatest amount of loss is produced in EXP1 (Fig. 10a). The amount of loss produced by CHEM2D-H2O is reduced in EXP2 when the UARS-based climatological values of r^o are replaced with the Aura MLS monthly zonal mean H₂O (Fig. 10b), particularly between the 0.01 and 0.001 pressure levels. Both EXP2 and EXP3 results show similar amounts of loss in the upper mesosphere at high northern latitudes. This indicates that both CHEM2D-H2O and ECMWF parameterizations produce comparable results in the region where peak H₂O photolysis occurs. Figure 10c also indicates that the ECMWF parameterization used in EXP3 produces loss at high southern latitudes where no sunlight is present, unlike the CHEM2D-H2O results in EXP1 and EXP2.

To further characterize the performance of CHEM2D-H2O in NOGAPS-ALPHA, we compare 10-day forecast model H₂O fields with analyzed H₂O using five sets of simulations initialized 00:00 UTC on 5, 10, 15, 20, and 25 June 2007. Figure 11a plots vertical profiles of the global area-weighted mean difference between analyzed and forecast H₂O mixing ratios (denoted “A–F”) from all five sets. We find that the CHEM2D-H2O parameterization with UARS-based r^o values in EXP1 produces the largest mean values of A–F above the 0.1 hPa level, consistent with the excessive H₂O loss seen in Fig. 10. In contrast, CHEM2D-H2O with Aura MLS-based r^o values produces the smallest mean A–F values. This result holds true when we examine mean A–F values over separate latitude bands between 90° S–90° N (Fig. 11b–f). Figure 11 also shows that the ECMWF scheme in EXP3 generally produces larger values of A–F than the CHEM2D-H2O scheme in EXP2, particularly in the southern extratropics (Fig. 11b and c). This is due to the fact that the ECMWF scheme specifies photolytic loss of H₂O at the high southern (winter) latitudes despite the lack of sunlight. At high northern (summer latitudes) CHEM2D-H2O and ECMWF H₂O results are comparable.

Fig. 11. Mean differences between NOGAPS-ALPHA analyzed H₂O and 10-day forecast H₂O (A–F) based on forecast model simulations initialized 00:00 UTC on June 5, 10, 15, 20, and 25, 2007 using CHEM2D-H₂O with UARS-based reference state (EXP1), CHEM2D-H₂O with Aura MLS-based reference state (EXP2), and the ECMWF parameterization (EXP3). Results are presented for (a) the global area-weighted average A–F, (b) 60° S–90° S, (c) 30° S–60° S, (d) 30° S–30° N, (e) 30° N–60° N, and (f) 60° N–90° N.

The preliminary evaluation of forecast model results for the June 2007 period indicates that all of the 10-day forecasts tend to underestimate the H₂O mixing ratios in the northern extratropics (see Fig. 11e) compared to the analyzed MLS values above the 0.01 hPa level, regardless of the details of the photochemistry parameterization. It should be noted that the Aura MLS accuracy limits (± 0.5 ppmv) and broad (12–16 km) vertical resolution in the upper mesospheric H₂O retrievals (Lambert et al., 2007) may complicate the evaluation of forecast skill in this region. It should also be noted that the forecast model transport in the upper mesosphere is highly sensitive to the details of the parameterized gravity wave drag, and that these details remain poorly constrained by observations. Because the effective H₂O lifetime is comparable to transport timescales in the 0.1–0.01 hPa region, deficiencies in model transport may contribute to some of the disagreement between the observations and the 10-day forecast model simulations. The effects of model transport in general, and gravity wave drag in particular, on NOGAPS-ALPHA middle atmospheric H₂O simulations are currently under investigation.

Finally, to demonstrate the effect of the CHEM2D-H₂O and ECMWF photochemistry parameterizations on stratospheric water vapor, where the relevant photochemical time scales are much longer than in the mesosphere, the EXP1 and EXP3 simulations were extended out to day 90. Figure 12 compares zonal mean Δr values from EXP1 and EXP3 between 10–0.1 hPa on day 90. In general, we find that both schemes produce small increases in water vapor (0.25–0.5 ppmv) in the tropical upper stratosphere. A notable result in Fig. 12 is that the CHEM2D-H₂O scheme in EXP1 leads to relatively more photochemical loss of H₂O in the mesosphere compared to the ECMWF scheme in EXP3 and thus a drier upper stratosphere over the South Pole due to downward transport of mesospheric air at high winter latitudes. This result suggests that using a H₂O photochemistry parameterization with latitude and seasonal dependences may reduce the moist bias in mesospheric H₂O seen in ECMWF analyses (Feist et al., 2007), and thereby improve its representation of dry mesospheric air descending into the polar vortex during winter and spring. To address this issue further, we plan to compare NOGAPS-ALPHA water vapor analyses

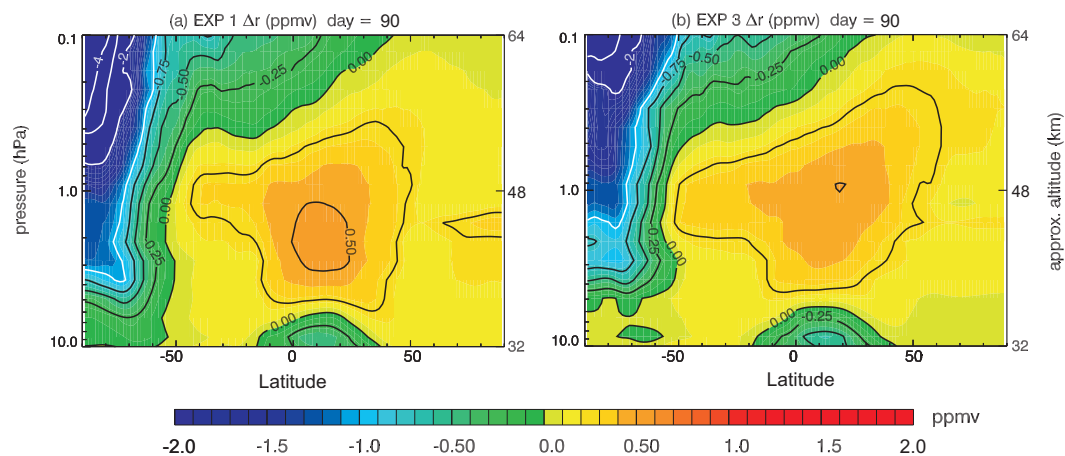

Fig. 12. Zonal mean values of the difference between NOGAPS-ALPHA prognostic H₂O and passive H₂O mixing ratio, Δr , on day 90 of (a) EXP1 and (b) EXP3 free-running NOGAPS-ALPHA forecast simulations initialized 00:00 UTC 5 June 2007.

from the full assimilations system using both the CHEM2D-H₂O and ECMWF parameterizations over the course of the entire season.

5 Conclusions

We have described and tested the new CHEM2D-H₂O parameterization for middle atmospheric water vapor photochemistry. CHEM2D-H₂O is based on output from a zonally averaged (2-D) model with full photochemistry and accounts for the latitude, altitude, and seasonal dependences in the production and loss terms due to CH₄ oxidation and H₂O photolysis, respectively. The parameterization is valid up to lower thermospheric altitudes of ~ 95 – 100 km.

A series of 10-day NOGAPS-ALPHA forecast model simulations with parameterized H₂O photochemistry were performed for the June 2007 period to evaluate the model's prognostic capability for middle atmospheric H₂O. The forecast model H₂O mixing ratios were compared with NOGAPS-ALPHA analyzed H₂O fields based on assimilation of Aura MLS profile measurements. We find that the CHEM2D-H₂O and ECMWF parameterizations both perform comparably at all altitudes below the 0.1 hPa level. Above this level, we find that CHEM2D-H₂O performance is dependent on the choice of the reference state mixing ratio distribution. In the June 2007 case examined here, using CHEM2D-H₂O with a reference state mixing ratio distribution based on the monthly zonal mean Aura MLS H₂O from the June 2005–2008 period produced the best overall agreement with the analyses. Middle atmospheric water vapor mixing ratios were lower in the early 1990's and exhibited significant positive trends during the UARS time period (e.g., Nedoluha et al., 1998; Randel et al., 1999). Therefore it is not surprising that the use of

the UARS H₂O climatology to specify r^o in EXP1 leads to a systematic underprediction for the June 2007 period analyzed here.

These preliminary results show that the latitude and seasonal dependences of the CHEM2D-H₂O parameterization can offer an improved 10-day forecast of upper mesospheric water vapor compared to the 1-D parameterization currently used in some operational NWP/DA systems. We are now carrying out a more formal evaluation of middle atmospheric H₂O prognostic skill in NOGAPS-ALPHA over a longer time period using the fully coupled NWP/DA system, which will provide a more complete and objective assessment of CHEM2D-H₂O performance. Future work will combine NOGAPS-ALPHA prognostic H₂O and temperature fields in order to predict supersaturation conditions that lead to the formation of polar mesospheric clouds. The role of additional physical processes such as molecular diffusion, which is not currently accounted for in either the CHEM2D or NOGAPS-ALPHA model, will also be investigated.

The CHEM2D-H₂O parameterization is freely available for research purposes. For more details, please contact the lead author.
